Lyme Disease

Laboratory Support of Diagnosis and Management

CLINICAL BACKGROUND

Lyme disease is by far the most common tick-borne disease in the United States. It is caused by the bacterium *Borrelia burgdorferi* and transmitted from the deer tick (*Ixodes scapularis* or *Ixodes pacificus*). Since 2008, approximately 30,000-40,000 cases of Lyme disease have been reported to the Centers for Disease Control and Prevention (CDC) every year, with most cases occurring during the summer months. In 2019 there were about 35,000 confirmed and probable cases of Lyme disease based on reports submitted by healthcare providers; however, the incidence is likely much higher based on insurance records.

Lyme disease cases are heavily centered in New England and the Mid-Atlantic. However, they are also found in Wisconsin and Minnesota and, to a lesser extent, other states in the Great Lakes and Pacific Coastal regions. Lyme disease is most common among children and middle-aged adults.

The clinical presentation of Lyme disease is categorized as 1 of 3 stages: early localized, early disseminated, and late (Table 1). In 70% to 80% of infected persons, early localized disease is characterized by erythema migrans (EM), a round skin lesion ≥5 cm in diameter that may appear in a "bulls-eye" pattern. In the absence of EM, the differential diagnosis may include other tick-borne diseases such as *Borrelia miyamotoi* disease, which is often misdiagnosed as Lyme disease owing to overlapping symptoms.

The first sign of early disseminated disease is often additional smaller lesions that may develop if Lyme disease is untreated; however, a recognized skin lesion does not always occur. Extracutaneous involvement in early disseminated disease can include the musculoskeletal, cardiac, or nervous systems.

In late-stage disease, Lyme carditis may overlap temporally with Lyme neuroborreliosis, a neurologic manifestation marked by symptoms such as cognitive impairment and memory difficulties. About 10% to 15% of patients with untreated Lyme disease develop late-stage disease.

### Table 1. Lyme Disease: Stages, Symptoms, and Recommended Laboratory Testing

<table>
<thead>
<tr>
<th>Stage of disease</th>
<th>Symptom onset</th>
<th>Symptoms</th>
<th>Laboratory testing</th>
</tr>
</thead>
</table>
| Early localized  | 3 to 30 days after tick bite | • EM  
• Fever, myalgia, headache, nausea, fatigue | <2 weeks after the onset of symptoms: if skin lesions that are atypical for EM or a mixed infection (eg, Lyme disease and *B. miyamotoi* disease) is clinically suspected, tick-borne PCR panel may be useful in the diagnosis of tick-borne disease |
|                  |              |          | 2 to 4 weeks after the onset of symptoms: acute (symptomatic) and convalescent (recovered) 2-tiered* IgG, IgM serology (if skin lesions that are atypical for EM) |
| Early disseminated| 2 weeks to months after tick bite | • Atrioventricular heart block sometimes with myopericarditis  
• Migratory pain in joints, bone, and muscle  
• Secondary annular lesions  
• Malaise, fatigue | 2 to 4 weeks after the onset of symptoms: acute and/or convalescent 2-tiered* IgG, IgM serology |
|                  |              |          | >4 weeks after the onset of symptoms: acute and/or convalescent 2-tiered* IgG serology |
| Late-stage       | Months to years after tick bite | • Encephalopathy, polyneuropathy, lymphocytic meningitis  
• Prolonged, chronic arthritis  
• Lymphocytoma  
• Fatigue | Acute and/or convalescent 2-tiered* IgG serology in serum; consider serology and/or detection of *B. burgdorferi* DNA in CSF or synovial fluid |

CSF, cerebrospinal fluid; EM, erythema migrans; PCR, polymerase chain reaction.

* 2-tiered testing is a follow-up of a positive or equivocal ELISA with an immunoblot test (standard 2-tiered test) or a second ELISA (modified 2-tiered test), as recommended by the CDC and the Association of State and Territorial Public Health Laboratory Directors.
Lyme disease will develop Lyme neuroborreliosis.\textsuperscript{17} Lyme arthritis may also occur during late-stage disease and is the most common manifestation of Lyme disease months after initial tick exposure.\textsuperscript{18} Left untreated, Lyme arthritis usually affects the knees over a period of several years.\textsuperscript{18}

If initiated in the early stages of Lyme disease, treatment with appropriate antibiotics is usually effective.\textsuperscript{9} Prophylaxis or serologic testing after a tick bite is usually not indicated in areas where less than 20% of ticks are infected; however, in areas where infected ticks are endemic, laboratory testing, including tick identification, is recommended.\textsuperscript{9,19} This Clinical Focus provides information on appropriate test selection and interpretation in patients with suspected Lyme disease.

The information in the text and table is provided for informational purposes only and is not intended as medical advice. Test selection and interpretation, diagnosis, and patient management decisions should be based on the physician’s education, clinical expertise, and assessment of the patient.

**INDIVIDUALS SUITABLE FOR TESTING**

- Symptomatic (Table 1) individuals with a history of exposure to a tick-endemic area

**TEST AVAILABILITY**

Laboratory tests that can help confirm the clinical diagnosis of Lyme disease include various serologic techniques and polymerase chain reaction (PCR)-based assays, as summarized in Table 2.

**TEST SELECTION AND INTERPRETATION**

A timeline of tick exposure in a tick-endemic area and symptoms of Lyme disease guide appropriate test selection.\textsuperscript{1,5,12} The CDC recommends testing for IgM or IgG antibodies using 2-tiered tests: a standard 2-tiered test (STTT) or a modified 2-tiered test (MTTT).\textsuperscript{15,16} It is reported that MTTT detects up to 30% more cases compared to STTT in patients with early Lyme disease.\textsuperscript{21,22} PCR is recommended for some non-Lyme, tick-borne diseases (eg, *Borrelia miyamotoi* disease, Powassan virus infection, and anaplasmosis) that are included in Lyme disease differential diagnosis.\textsuperscript{12,13,23-26} The sections below outline appropriate test selection based on the stage of disease along with characteristic test results.

**Early localized Lyme disease**

Diagnosis of early localized Lyme disease can sometimes be made on the basis of EM alone without laboratory testing.\textsuperscript{3,20} The Infectious Diseases Society of America (IDSA) suggests that PCR methodology not be used for the diagnosis of Lyme disease.\textsuperscript{19} However, in patients at less than 2 weeks after symptom onset, PCR may be helpful to identify non-Lyme tick-borne diseases if there is diagnostic uncertainty or if mixed infection is suspected.\textsuperscript{11-13,23-26} Two-tiered testing should be used 2 to 4 weeks after the onset of symptoms; an increase in IgM titers may not be detected in specimens collected within 2 weeks following a tick bite.\textsuperscript{5,27} IgM antibodies may be present within a few weeks of disease onset, whereas large increases in IgG titers are produced months later; thus, 2-tiered testing that is positive for IgM and negative for IgG indicates early infection.

**Early disseminated Lyme disease**

Two-tiered testing is recommended when clinical findings are suggestive of early disseminated Lyme disease (Table 1).\textsuperscript{5,11} For specimens collected at 2 to 4 weeks after onset of symptoms, 2-tiered testing that is positive for IgM and negative for IgG indicates early infection, unless obtained on a specimen collected more than 1 month after onset of symptoms. If the specimen was collected more than 1 month after onset of symptoms, a positive IgM finding is more likely to represent a false-positive result unless IgG is also positive; vaccination or other diseases may also cause false-positive results. A positive IgG result by 2-tiered testing is required to confirm the diagnosis of early disseminated Lyme disease, but does not differentiate between active and past *B burgdorferi* infection.\textsuperscript{11,28}

Negative serology results may indicate lack of infection or lack of seroconversion, which may occur if samples are collected too early after disease onset or when early antibiotic therapy blunts the antibody response. PCR-based assays can be useful in the workup of *B burgdorferi* infection if seroconversion has not yet occurred; these assays, however, are limited by low clinical sensitivity (18%).\textsuperscript{29} Untreated patients who continue to be symptomatic but are seronegative for 6 to 8 weeks are unlikely to have Lyme disease, and a differential diagnosis should be considered.\textsuperscript{19}

**Late-stage Lyme disease**

In patients with suspected Lyme disease that has been left untreated for months to years after a tick bite, symptoms that are characteristic of late-stage disease such as Lyme arthritis or Lyme neuroborreliosis can help guide diagnostic test selection. Detection of *Borrelia* DNA in synovial fluid, commonly from the knees, supports the diagnosis of Lyme arthritis (sensitivity, 78%; specificity, 100%).\textsuperscript{18,29} A diagnosis of Lyme neuroborreliosis can be supported if *Borrelia* antibody or DNA are detected in cerebrospinal fluid (CSF). Antibody levels in CSF can be measured by ELISA or nephelometry and compared to control levels (ie, serum antibody or albumin) in a ratio defined as an antibody index; an elevated antibody index strongly supports a diagnosis of Lyme neuroborreliosis.\textsuperscript{30} *Borrelia* DNA in CSF can be detected by PCR-based assays, which can support a diagnosis of Lyme neuroborreliosis; however, detection by PCR may be limited owing to low clinical sensitivity (38%).\textsuperscript{31}
